

Exercise 4

Using Docker

Prior Knowledge

Unix command-line

Apt package manager

Amazon AWS / EC2 Console

Learning Objectives

Be able to instantiate docker containers

Be able to modify docker containers and save them

Interacting with the docker hub

Creating a dockerfile

Running a docker container on EC2

Software Requirements

- AWS
- Docker
- Docker-Machine
- Ubuntu
- Nano text editor

Introduction

This lab consists of three parts. The first part is just playing around with Docker to understand how stuff works. The things we are going to do are not typical docker usage as we are investigating the way the system works

The second part involves creating a dockerfile which is a sort of build file. This is the more usual usage of Docker and will stand you in good stead for many projects.

Finally we will load your newly created docker image up in EC2.

PART A - understanding the Docker model

1. Let's start by running a CentOS image inside our Ubuntu VM.
2. From the Ubuntu command-line, type:
`docker pull centos`

(You may need to enter the oxclo password which is **oxclo**)

3. You should see something like:

```
latest: Pulling from centos
47d44cb6f252: Pull complete
168a69b62202: Pull complete
812e9d9d677f: Pull complete
4234bfdd88f8: Pull complete
ce20c473cd8a: Pull complete
centos:latest: The image you are pulling has been verified.
Important: image verification is a tech preview feature and
should not be relied on to provide security.
Digest:
sha256:c96eeb93f2590858b9e1396e808d817fa0ba4076c68b59395445cb957b
524408
Status: Downloaded newer image for centos:latest
```

4. We will take a look at what this means shortly, but first let's try it out.
`docker run -ti centos /bin/bash`

Hint:

-ti basically means run this container in interactive mode. For more explanation see: <https://docs.docker.com/engine/reference/run/>

You should see:

```
[root@c22c9c908236 /]#
```

Did you notice how fast it started?! This is not your usual VM.

Let's refer to this window as the *docker window*.

5. Now type
`ls /home/oxclo`

This will fail, because we are now in a mini virtual machine. Now try

`apt-get`

Again it fails. But what about yum?

Why does yum succeed? Because yum is the package manager for CentOS and now we are in a CentOS world. (Actually we won't use yum or apt-get *within* the docker... we'll come to how that works shortly).

6. Start a separate window. Let's refer to this as the *control window*. Now type

`docker ps`

7. You will see something like:

CONTAINER ID	IMAGE	COMMAND	CREATED
STATUS	PORTS	NAMES	
c22c9c908236	centos:latest	"/bin/bash"	10 minutes ago
Up 10 minutes		drunk_engelbart	

8. Docker has given your container instance a random name (in my case `drunk_engelbart`). You can now see how this instance is doing:

`docker stats drunk_engelbart`

Obviously change *drunk_engelbart* to the name of your container!

9. Notice how little memory each container takes.
10. Now **Ctrl-C** to exit that command.
11. Now go onto <http://hub.docker.com> and signup. You need a valid email address to complete signup. I think you might want to do this in your own name because it's a useful system.
12. Once you have signed up, then do a docker login:
`docker login -u yourdockerhubuserid`
13. Back in the control window, type

`docker commit <your_container_name> <yr_dock_id>/mycentos`

e.g.

```
docker commit drunk_engelbart pizak/mycentos
```

14. Now list the images you have locally

```
docker images
```

15. You will see something like:

REPOSITORY	TAG	IMAGE ID	CREATED	VIRTUAL SIZE
pizak/mycentos	latest	9f154062124f	21 minutes ago	172.3 MB
centos	latest	ce20c473cd8a	5 weeks ago	172.3 MB

16. Actually it would be useful to give that image a version name:

```
docker tag pizak/mycentos pizak/mycentos:1
```

17. Repeat the “docker images” command.

18. Now let’s push that image up to the docker hub:

```
docker push pizak/mycentos:1
```

Enter your docker hub credentials when prompted.

19. The system will whirr away and upload some stuff. Eventually you will see something like:

```
The push refers to a repository [pizak/mycentos] (len: 1)
9f154062124f: Image already exists
ce20c473cd8a: Image successfully pushed
4234bfdd88f8: Image already exists
812e9d9d677f: Image already exists
168a69b62202: Image successfully pushed
47d44cb6f252: Image already exists
Digest:
sha256:f751347496258e359fdc065b468ff7d72302cbb6f2310adee802b6c5ff92615d
```

20. Now let’s go back to the original docker window, where your image is still running. Make a new file in home like this:

```
[root@482fe4e23a8b /]# cd home
[root@482fe4e23a8b home]# echo hi > hi
[root@482fe4e23a8b home]# ls
hi
```

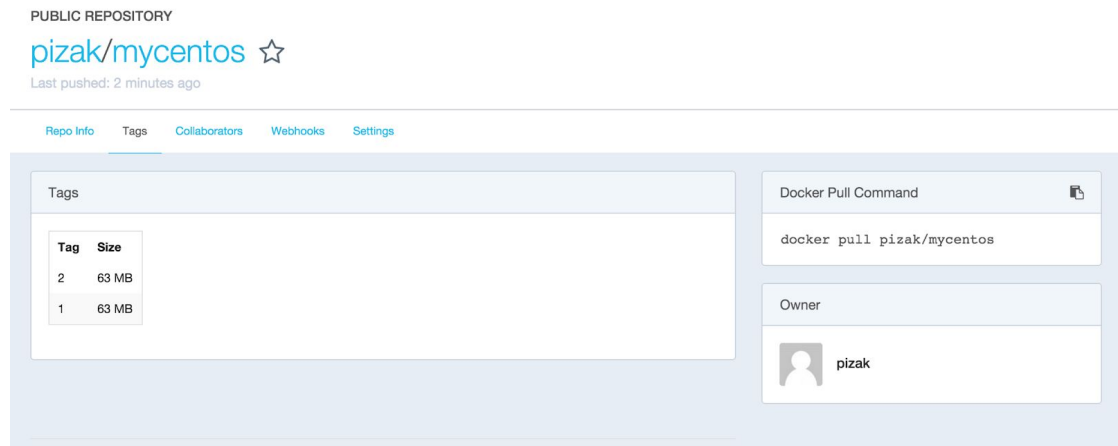

21. Now in your control terminal you can commit this change:

```
docker commit drunk_engelbart pizak/mycentos:2
```

22. Let’s push that image you’ve just made up to the Docker hub:

```
docker push pizak/mycentos:2
```

23. Notice how this time only a few bytes were uploaded. This is because of the layered file-system that docker uses to only save incremental changes. It is one of the major benefits of the docker system.
24. Go to the docker website <http://hub.docker.com> and view your repositories. In particular look at the tags tab:

25. You can now pull this docker image and create a container anywhere you like. Let's try some stuff out. From your *docker window* first exit the container by typing exit or Ctrl-D.

26. Now let's start v1 of your container:

```
docker run -ti pizak/mycentos:1 /bin/bash
```

Try looking at the home directory:

```
ls /home
```

Now exit and load version 2

```
docker run -ti pizak/mycentos:2 /bin/bash
ls /home
```

27. To prove that this is saved in the docker repo, do the following:

First delete all the images locally that were tagged with your userid:
(Replace pizak with your userid)

```
docker rmi -f $(docker images -q pizak/*)
```

28. Now try to start v2 again. You will see that docker automatically re-downloads this and then runs it. Check that your file exists in the /home directory.

29. The one thing we haven't yet seen is how to get a docker image to do something vaguely useful.

30. First check you have nothing running locally on port 80. Browse to <http://localhost:80> It should fail.

31. Now in your docker window, type:

```
docker run -p 80:80 httpd
```

32. You should see a bunch of stuff like this:

```
Unable to find image 'httpd:latest' locally
latest: Pulling from httpd
ef2704e74ecc: Pull complete
1d6f63d023f5: Pull complete
...
781a5fd1cabf: Pull complete
bbd8adcb3ad5: Pull complete
6f953eead92f: Pull complete
afa235ca0577: Pull complete
f6d0a9cc3857: Pull complete
3fdd2b382f43: Pull complete
httpd:latest: The image you are pulling has been verified. Important:
image verification is a tech preview feature and should not be relied
on to provide security.
Digest:
sha256:fe40d6cb973ad7acbbc5fa99867efc03474649250a54da002fddaa88c6a5ff2f
Status: Downloaded newer image for httpd:latest
AH00558: httpd: Could not reliably determine the server's fully
qualified domain name, using 172.17.0.11. Set the 'ServerName'
directive globally to suppress this message
AH00558: httpd: Could not reliably determine the server's fully
qualified domain name, using 172.17.0.11. Set the 'ServerName'
directive globally to suppress this message
[Fri Nov 20 14:08:08.239803 2015] [mpm_event:notice] [pid 1:tid
140576655767424] AH00489: Apache/2.4.17 (Unix) configured -- resuming
normal operations
[Fri Nov 20 14:08:08.239940 2015] [core:notice] [pid 1:tid
140576655767424] AH00094: Command line: 'httpd -D FOREGROUND'
```

33. Now browse <http://localhost:80> again and you should see.

It works!

34. *Are you wondering what -p 80:80 means?*

It means expose port 80 from within the container as port 80 in the host

system.

35. Now kill that container (Ctrl-C) and start it again in detached mode.
This is how you would normally run a docker workload.

```
docker run -d -p 80:80 httpd
```

36. To find your docker runtime try

```
docker ps
```

CONTAINER ID	IMAGE	COMMAND	CREATED
STATUS	PORTS	NAMES	
f9ed00d6c251	httpd:latest	"httpd-foreground"	5 seconds
ago	Up 4 seconds	0.0.0.0:80->80/tcp	
reverent_lalande			

and finally to stop it

```
docker kill reverent_lalande
```

Recap:

In this section we have learnt basic docker commands including run, ps, image, commit, push and pull. We have learnt about the layered file system, and also about the docker repository.

We have looked at exposing network ports, how to start detached workloads and how to kill them.

In particular, notice how the docker containers seem like processes, but with the complete configuration neatly packaged and contained within a single packaged system that can be versioned, pushed and pulled. This model is ideal for creating and managing *microservices*.

PART B – creating a Dockerfile

37. While I can imagine it might be possible to create docker images by modifying them like we have and then saving them, this is not a repeatable easy to use approach. Instead we want to build a dockerfile in a repeatable way.

38. Make a new directory (e.g. ~/dockerbuild)
Change to that directory and edit a file there called Dockerfile

39. Copy and paste the contents of this Dockerfile into it:
<http://freo.me/oxclo-dockerfile>

40. Save it.

41. Build it:

From the command line (in the correct directory) execute:

```
docker build -t <your_docker_id>/nodeapp:1 .
```

42. While it is building, take a look at the docker file and also the reference guide:
<https://docs.docker.com/engine/reference/builder/>

43. Once it has built, try running it:

```
docker run -d -p 80:8080 <yrdockerid>/nodeapp:1
```

44. Browse <http://localhost:80> and you should see:

45. Finally, push your newly created docker image into the cloud:

```
docker push <yrdockerid>/nodeapp:1
```

Congratulations, you have completed part B.

PART C – Running your docker in the cloud

46. There is an Amazon Elastic Container Service for running containers. This provides their own container orchestration model, alternative to Docker Swarm and Kubernetes. However, we are going to use Docker Machine and Docker to start our systems instead, giving us a portable approach.
47. If you already did Exercise 1, then your AWS credentials should be stored in `~/.aws/credentials`. Docker Machine uses those so you don't need to set any environment variables.
48. Type:
- ```
docker-machine create \
 -d amazec2 \
 --amazec2-region eu-west-1 \
 --engine-install-url=https://freo.me/getdocker \
 --amazec2-security-group web-server-sg \
 oxcloXX-docker
```

This ensures our server will run in Ireland, and use our security group. The instance will be called `oxcloXX-docker`.

*There is currently a bug in using the latest docker with AWS which is fixed by the engine-install-url.*

You should see:

```
Running pre-create checks...
Creating machine...
(oxclo01-docker) Launching instance...
Waiting for machine to be running, this may take a few minutes...
Detecting operating system of created instance...
Waiting for SSH to be available...
Detecting the provisioner...
Provisioning with ubuntu(systemd)...
Installing Docker...
Copying certs to the local machine directory...
Copying certs to the remote machine...
Setting Docker configuration on the remote daemon...
Checking connection to Docker...
Docker is up and running!
To see how to connect your Docker Client to the Docker Engine
 running on this virtual machine, run: docker-machine env
 oxclo01-docker
```

49. Go to the AWS Console and you should see an EC2 instance now running.
50. Follow that last suggested command:

```
docker-machine env oxcloXX-docker
```

You should see:

```
export DOCKER_TLS_VERIFY="1"
export DOCKER_HOST="tcp://54.246.240.90:2376"
export
DOCKER_CERT_PATH="/home/oxclo/.docker/machine/machines/oxclo0
1-docker"
export DOCKER_MACHINE_NAME="oxclo01-docker"
Run this command to configure your shell:
eval $(docker-machine env oxclo01-docker)
```

51. Once again, do as asked:

```
eval $(docker-machine env oxcloXX-docker)
```

52. Now when you run docker commands, they will no longer act locally on your Ubuntu VM, but instead on the AWS instance you've just started.

53. Now run the docker container again:

```
docker run -d -p 80:8080 <yrdockerid>/nodeapp:1
```

54. You can find the address of the AWS instance using:

```
docker-machine ip oxcloXX-docker
```

or by looking in the AWS console

55. Open a browser window and check you can access the app (running on port 80)

56. You can also SSH into the server using:

```
docker-machine ssh oxcloXX-docker
```

57. Try that. When you are finished type

```
logout
```

58. To terminate the instance, type:

```
docker-machine rm -f oxcloXX-docker
```

59. Check that the instance is now terminating in the AWS console.

60. Docker Machine will have automatically created a new key pair for this server (which is not ideal....). To tidy up, let's remove that:

```
aws ec2 delete-key-pair --key-name oxcloXX-docker
```

*Recap: What we have done is to take the container-ised application we built on our local machine and then deploy it automatically to EC2. While this looks a bit similar to using userdata (which we did in a previous exercise), in fact this is much more replicable because we can test and deploy our docker image on many different systems. For example, if you sign up to the Github Student deal, you get free credit on DigitalOcean, and with a very similar model you could run the same docker code on there.*

## Extension

If you have a github or bitbucket account, you can put the Dockerfile into the repository and automatically build it. Have a go.

Some rough hints:

Create a new public repository and place the Dockerfile in the root directory.

In <http://hub.docker.com> go to Settings (click on your username)

Choose Linked Accounts and Services

Link to your Github account. Choose the "Public and Private"

Now click on Create (next to search) and Create Automated Build.

Select your github repository.

Enter a description. Click Create.

Now check the build status in the Build details tab. It takes about 3 minutes to build. If its not building you can manually trigger it from the build settings.

Try doing an update to your dockerfile (maybe a spare comment) and then git push.
